Background: The modified early warning score (MEWS) was set up to supply prompt recognition of clinically deteriorating patients before they undergo a severe and life-threatening event. The study aimed to describe the probable usefulness of the MEWS in identifying deteriorating post-Whipple patients in hospital wards.

Methods: We performed a study to analyze the relationship between the vital parameters and postoperative severe adverse events of patients after Whipple surgery in Guangdong Provincial People's Hospital from 2000 to 2017. In the retrospective study, a total of 13,651 sets of vital parameters in 236 Whipple postoperative patients were included. Subsequently, we applied a MEWS scoring system and explored the accuracy of the MEWS in evaluating the patients' final events versus advanced mathematical models. We then put the MEWS into the ward warning system and confirmed the accuracy of the MEWS based on the results of prospective studies again.

Results: We assessed the ability of the MEWS to predict postoperative complications with an accuracy rate of 90.86–91.23%, a sensitivity of 83.04–90.88%, and a specificity of 90.85–95.73%.

Conclusions: The MEWS model was applied to identify post-Whipple patients at risk of complication. Once the MEWS ≥2, interventions were needed to minimize the adverse events. Our data suggest that the MEWS is comparable to the advanced mathematical models, but MEWS is more accessible to perform and more generally applicable.

Keywords: Detection of deteriorating patients; vital parameters; modified early warning score (MEWS)

Introduction

It is challenging to identify ward patients who are in danger of deterioration. In the earlier literature, through the observation of cases, Goldhill emphasized the importance of physiological abnormality as a marker for a person whose condition dramatically worsens (1). Thus, the early warning system was conceived, and, depending on the actual situation in different countries and departments, the modified early warning scores (MEWS) was created. Moreover, the MEWS is intended to improve communication between nursing staff and junior doctors and to respond to patients who need to be given immediate priority. Louise indicated that adherence to the MEWS protocol is essential (2). Some studies have illustrated that the risk of death increased with
an increasing MEWS score (3-5). However, Vorwerk voiced concerns about the tendency of low MEWS stratification to create type II errors (6).

In a UK cohort study, after the use of MEWS, the number of cardiac arrest calls relative to adult hospital admissions, the proportion of patients admitted to intensive care, and the in-hospital mortality of these patients fell dramatically (7). It also found that the early detection of deterioration in patients on surgical wards outside the intensive care unit (ICU) should be improved by introducing an automated MEWS-based system with paging functionality (8), while other studies indicated that MEWS could enhance patient care and improve the efficient use of available clinical resources (9). Overall, the MEWS was more suitable for the evaluation of the prognosis of local patients than the traditional scale (10).

Our project aimed to predict the occurrence of complications in post-Whipple patients based on the MEWS. We usually performed Whipple procedure to remove a malignant tumor involving the ampulla of Vater, the terminal part of the common bile duct, the duodenum, or the head of the pancreas. It is also used to remove cystic pancreatic neoplasms that may be malignant or chronic calcified pancreatitis that causes intractable abdominal pain. However, post-Whipple severe complications should not be ignored because of the poor prognosis for patients, mainly manifested as prolonged discharge time, deteriorating condition, transfer to the ICU, or death. Therefore, early detection of postoperative complications is a significant means for prompt intervention and prevention of adverse outcomes.

The goal in our study was to provide the hospital staff with more attentions into the value of the MEWS in predicting their patients’ prognosis and thereby increase the awareness and protocol adherence.

Methods

Research center

The retrospective observational study and prospective confirmatory study were conducted in a large urban hospital medical center (Guangdong Provincial People's Hospital) where there are 110,000 admissions per annum in China.

Patient choice

In the 183-month inclusion period from January 2000 to March 2015, all post-Whipple surgery patients who were in the hospital at 07:00/10:00/13:00/16:00/19:00 and in the department of general surgery were included. Patients 18 years and older with more than one overnight stay were included. The Ethics Committee of Guangdong Academy of Medical Sciences Medical Center approved the study, and the necessity for informed consent was waived.

Data collection

According to the protocol, each time the vital parameters of the patients were obtained, the nurses were requested to record the vital parameters in the electronic system and determine the MEWS. The MEWS measurements could be repeated any time during the patients’ hospitalization by the nurses and doctors, and all the vital parameters were used for analysis. The professional investigators checked the charts of all included patients and determined whether the MEWS was documented and calculated correctly. We discarded all the incomplete data sets of vital signs and only included the complete set of vital signs measured at a given time, including respiratory rate (RR), heart rate (HR), systolic blood pressure (SBP), and temperature (TEM). Scores were recalculated by investigators using available data in the charts. Moreover, we found out all the patients’ post-operation regression and then calculated the relationship between the scores and the regression.

Follow-up

If the post-Whipple patients have bleeding, infection, pancreatic leakage, bile leakage, intestinal leakage, gastric emptying disorder, hypoalbuminemia, ICU admission, or died, we defined them has postoperative complications. All patients admitted during the study period were followed up from admission to final events after inclusion. Also, patients were followed up for 30 days after discharge to obtain information about the last events.

Advanced models

To further verify the accuracy of the MEWS, we used some more advanced models and algorithms for verification. It is necessary for a dichotomous problem to judge whether the patient with or without adverse events is based on the patient’s vital parameters. We divided the database, which includes 13,651 sets of vital parameters, into a 75% training set (n=10,238) and a 25% test set (n=3,413). By learning
the known sample training set, the binary classification algorithm finds the classification rules and predict the category of new data. At present, there are classification algorithms such as support vector machine (SVM), backpropagation (BP) artificial neural network (ANN), decision tree (DT), and so on.

**SVM model**

SVM is used to solve the problem of linear separability (Figure 1A). If in the case the data is linearly inseparable, SVM will move from a low-dimension input space to a higher dimension space using a nonlinear mapping algorithm (Figure 1B). The use of a higher dimension makes a linear analysis of nonlinear characteristics in the sample possible. It is also based on the structural risk minimization theory to construct the best hyperplane in the feature space so that the learner is globally optimized, and the expectation in the entire sample space meets specific upper bound with some probability. We set up the RR, HR, SBP, and TEM as vectors in four different dimensions. Each set of data has four different vectors and one outcome variable.

**ANN model**

BP ANN is a multilayer feedforward network trained by error BP (Figure 1C). Its basic premise is a gradient descent method. The basic BP algorithm includes the forward propagation of signal and backward propagation of error. The error output is calculated in the direction from input to...
output, while the weight and threshold are adjusted in the
direction from output to input. In the forward propagation,
the input signal acts on the output node through a hidden
layer. After the nonlinear transformation, the output signal
is generated. The error BP is transmitted back to the output
error back layer by layer to the input layer through the
hidden layer and distributes the error to all the units in each
segment. By adjusting the connection strength of the input
node and hidden layer node, and the connection strength
and threshold value of the hidden layer node and the output
node, the error decreases along the gradient direction. After
repeated learning and training, the network parameters
(weights and thresholds) corresponding to the minimum
error are determined, and the practice is stopped. At this
point, the trained neural network can process the non-linear
transformation information with the minimum output error
for the input information of similar samples.

A neural network with a single hidden layer is modeled
using the R language n-net package. Four input layer
neuron nodes were set according to the four factors of RR,
HR, SBP, and TEM. A three-layer neural network with a
hidden layer can already approach any nonlinear function,
so setting a hidden layer can simplify the calculation process
of the model and achieve a better prediction effect (the
number of nodes in a single hidden layer, which called “size”
is 5). The hidden layer and the output layer use a logical
activation function. The activation function is a T ansig
function, and its expression is f(x)=2/(1+e^(-2x))-1. The
patient's critical scores and eventual regression identification
is a binary classification problem, so the output layer has a
neuron node.

DT model
DT is a decision analysis method based on the known
likelihood of various situations. It is used to calculate the
probability of net present value greater than or equal to zero
to evaluate project risk and to judge its feasibility. The DT
consisted of a series of nodes from the top of the tree to the
root node at the start, and each node is a decision or split
points. According to the input value a condition is set, if the
vital parameters meet the conditions, the left or the right
path is taken. This process continues until the screening of
all states for all the inner nodes is complete and reaches the
bottom leaf nodes; the output of a certain value is our forecast
results. We use the C5.0 algorithm to construct the DT,
which was evaluated on training data (n=10,238, Figure 1D).
The system selected size of 13, and of the cases, there are
about 507 errors that account for 5%.

Statistical analysis
Descriptive characteristics and frequencies were calculated
in SPSS version 22.0. The SVM, BP ANN, and DT models
were built and tested using Rstudio 3.5.1 for Windows 64-
bit. Continuous variables are summarized by mean and
standard deviation since data were distributed normally.
There was a minute number of untruthful parameters in the
database, and these parameters were normal.

We defined the RR, HR, SBP, and TEM as four
variables, and used the SVM, ANN, and DT models to
analyze the combination between the MaxScores and final
events in each group’s variables. We take the accuracy,
sensitivity, specificity, positive predictive value (PPV),
negative predictive value (NPV), type I error, type II error,
the area under the curve (AUC) as the evaluation indexes of
the models.

Prospective confirmatory study
Then from Apr. 2015 to Sep. 2017, we used the MEWS
to predict the incidence of postoperative complications
according to the 2,211 integrated vital parameters of 79
post-Whipple patients, which allowed us to detect and
intervene in the patients’ abnormalities at once. According
to the procedure of the retrospective study, we analyzed the
prospective study in the same way.

Results
Patient characteristics
From January 2000 to March 2015, a total of 236 patients
comprising 13,651 groups of integrated vital parameters,
participated in a 183-month inclusion period of historical
statistics (Figure 2 and Table S1).

MEWS protocol in our institution
Four basic vital parameters were considered in an easy-
to-use algorithm (Table 1). The range for the MEWS
was between 0 and 8. We distributed a protocol card and
extensively trained the staff during the implementation of
the protocol.

Establishment of Max-MEWS
To determine the largest score of this scale, we used the
receiver operating characteristic (ROC) curve to observe
Figure 2 The frequency distribution of vital parameters in post-Whipple patients in the retrospective study (n=13,651).

1. Determine MEWS—MEWS ≥2 contact clinician on duty; 2. clinician on duty assess patient <30 min and draft a plan for treatment; 3. effect of therapy is analyzed <60 min; 4. if no effect of treatment—clinician on duty or nurse contacts the rapid intervention team (RIT); 5. Document aberrant parameters in the patient’s charts. MEWS, modified early warning score.

Each value (Figure 3) and found that MEWS =2 was the best choice (Table S2). Consequently, a total score of 2 or higher was considered a critical score. MEWS was calculated by hand and electronically documented on the patients’ charts. Once a patient reached a critical MEWS (≥2), the nurses would contact the doctor on duty at once. The doctor would then assess the patient within 30 minutes, and draft a plan for treatment, evaluate this within 60 minutes, or call a rapid intervention team (RIT).

Measuring and documentation

There was a total of 13,651 sets of data included in the retrospective observational study. Figure 4 displays a flowchart of the measurement and documentation. After the frequency analysis of the data, MEWS was set up according to the results obtained, and the number of people with different scores and different outcomes was calculated. Then we set up the distribution of the confusion matrix under MEWS in the retrospective study (Table S3).
Models calculation

According to Table 2, the prediction accuracy of MEWS is up to 90.86%, sensitivity is 90.88%, specificity is 90.85%, type I error is 9.15%, and type II error is 9.12%.

The prediction accuracy of the linear kernel (LK) SVM model was about 90.36%, the sensitivity was about 85.97%, and the specificity was about 93.27% (Table 2). To improve the quality of the SVM model, we used the radial basis function kernel (RBFK) SVM model and calculated the similar evaluation index (Table 2). The prediction accuracy of the RBFK SVM model was about 92.03%, the sensitivity was about 87.44%, and the specificity was about 95.08%. Finally, we have set up the corresponding confusion matrix (Table S4).

The accuracy of the neural network model and other indicators are highly volatile and have a wide range of fluctuations, and the training time of the model is much longer than that of the MEWS. Selecting a neural network model with accuracy near the median can represent the general situation of the neural network model under the existing parameter settings. We ran the BP ANN model 200 times to get the best solution and get the characteristic of each evaluation indicator (Table S5). The prediction accuracy of the BP ANN is about 92.56%, and the sensitivity is about 89.05%, the specificity is about 94.88%.

Prospective confirmatory study

We investigated the patient characteristics of the prospective study (Table S8) and drew the corresponding frequency distribution diagram (Figure 6). Moreover, we drew a ROC and calculated each statistical parameter to find the optimal solution in the prospective confirmatory studies between MEWS, SVM, BP ANN, and DT (Figure 7 and Table 2).

Discussion

To able to ignore the individual errors arising from measuring vital parameters at various times caused by the fluctuation of the diverse human body, we used big data to generate a conclusion. At a large, Chinese government
hospital, we used the MEWS to accurately predict postoperative outcome in 90.86–91.23% of general surgery ward post-Whipple patients. We found that MEWS was a sensitive predictor of adverse events in patients; patients with a MEWS ≥2 were prone to complications such as bleeding, infection, leakage, gastric emptying disorder, hypoalbuminemia, and so on. With a MEWS <2, the patient usually recovered and was discharged within 2 weeks after surgery.

The LK SVM model involves a parameter related to the model error budget, called “cost”. According to Table S9, we discover that adjusting the cost parameters will not fundamentally improve the fitting quality, but significantly increase the training cost. Therefore, we take cost = 1 and build the confusion matrix of the LK SVM. To improve the quality of the SVM model, we used a positive gamma parameter for nonlinear computing. The gamma parameter is used to control the locality of similarity calculated between its two vector inputs. If the gamma value is too significant, it is easy to produce an amount close to 0, and if the gamma value is too small, it is easy to include more distant vectors in the calculation. To balance the bias and the variance, we take cost = 1 and gamma = 1 for the RBFK SVM model.

Because the neural network contains a random component in the form of weight vector initialization, it is unlikely to obtain the same result after repeated use of the neural network, even if the obtained BP ANN model does not converge and cannot be used for the “bi-directional early warning study”.

The MEWS we designed judged the four parameters, which could be considered as equally essential and then sum them up to determine whether the result of the post-Whipple patients was have adverse events (HAE) or no adverse events (NAE). The DT model shows the relative importance of four indexes in the classification process step.

by step. If the degree of RR1 used is considered 100%, then the degrees of SBP1, HR1, and TEM1 used are 68.40%, 51.00%, and 8.79%, respectively. As can be seen from the DT graph, RR1 is more often used than other indexes in the classification process. The DT is similar in form to MEWS, and it judges the range based on each index value, and then makes the next step. However, the DT also considers the importance between the different indexes in the classification process, so it has high prediction accuracy.

We used five models to evaluate retrospective observational studies, so we drew a ROC to find the best solution between MEWS, SVM, BP ANN, and DT. It is clear that the MEWS was the easiest to use, and its AUC on the test set was equal to that of the LK SVM (about 90%). The accuracy of RBFK SVM and BP ANN models on the test set (about 92%) was higher than that of the MEWS, but from the perspective of sensitivity, the MEWS had the highest sensitivity of the four models above. The DT had both the high prediction accuracy and specificity of LK SVM, RBFK SVM, and BP ANN and the high sensitivity of the MEWS model. However, the simplicity of the DT model was still not as good as the MEWS in real-time

Figure 6 The frequency distribution of vital parameters in the prospective study (n=2,211).

Figure 7 The ROC of the five models in the prospective confirmatory study. ROC, receiver operating characteristic; MEWS, modified early warning score; LK, linear kernel; SVM, support vector machine; RBFK, radial basis function kernel; BP, backpropagation; ANN, artificial neural network.
Moreover, our object of study was limited to post-Whipple outcomes, including ICU admission and cardiac arrest. Hospital inpatients have evaluated specific patient-important complications. Other studies of early warning scores among significant adverse outcome: the presence of postoperative complications. Medical personnel.

In prospective confirmatory studies, as an advanced MEWS, the DT still performed well among the statistical parameters. In contrast, LK SVM was the least correct in predicting post-Whipple complications of the five models in prospective studies. It is worth mentioning that RBK SVM had the highest specificity (98.60%, followed by DT 98.39%) and the lowest type I error (1.40%, followed by DT 1.61%) in prospective studies. However, this was not our primary outcome measure, because our focus in setting up a MEWS was to identify patients with a potential risk of post-Whipple complications, rather than patients without postoperative complications but with intensive intervention. Therefore, the scale designed should have high sensitivity and a lower type II error. The MEWS was in line with our expectations, with a high sensitivity of 83.04% and a small type II error of 16.96%, only inferior to DT and leading the other three advanced mathematical models. DT is still the most correct model that best conforms to the prediction of post-Whipple complications of patients due to its unique advantages of enumerating all permutations. However, there is no doubt that the use of DT has a high technical threshold and computing cost. The MEWS, with its simple and convenient operation, high sensitivity, and low type II errors comparable to the advanced mathematical models, will be the preferred model for medical staff to identify patients with postoperative complications in the first instance from the hospital bed.

The strengths of our study include its ambispective and observational design, and a large number of patient samples examined. We applied the MEWS across all adult post-Whipple surgical patients in Guangdong's largest government hospital, where the burden of illness, patient volume, and limited resources underscore the immense challenges of delivering added attention and management of medical personnel.

The study has several limitations. We evaluated only one significant adverse outcome: the presence of postoperative complications. Other studies of early warning scores among hospital inpatients have evaluated specific patient-important outcomes, including ICU admission and cardiac arrest. Moreover, our object of study was limited to post-Whipple patients in the general surgery ward. If we had extended the scoring to patients from more departments and more disease types, the results would be more useful, but this was not feasible due to resource restrictions. However, about 5% of a large number of patients in our department has required Whipple surgical treatment in recent years, so this study is of great significance in guiding perioperative patient management of Whipple surgery in general surgery wards around the world.

In published papers, most of the studies are retrospective analyses (3,7,8,10-13), and only a few are prospective studies (14-16). Most of the current publications are still used to assess whether patients need to be transferred to the ICU (14), and some of them are used for predicting the outcome of in-hospital cardiac arrest (12). Age was associated with an increase in the risk of death, and being on a medical ward rather than a surgical ward was associated with an increase in the risk of death (3). End-tidal CO$_2$ (EtCO$_2$) was another independent predictor of critical illness (17). The MEWS from all over the world have a sensitivity which generally fluctuates between 72.4% and 95.5%, and a specificity which fluctuates between 83.0% and 90.8% (11,14,16).

Timely identification of critical illness is a vital step towards establishing its overall burden in low-resource settings. This step can lay the foundation to evaluate interventions that minimize morbidity and mortality. Although Churpek's team found that several machine learning methods were more accurate for predicting clinical deterioration on the wards (18), guidelines and protocols used in high-income settings can be challenging to translate to settings with fewer resources, diverse patient populations, and various disease phenotypes. The MEWS, a simple scoring system formed of patients' vital signs, is an approach that can perform measurements at the bedside with minimal resources.

Conclusions

Our study performed in a real-life setting, and we proved that a MEWS ≥2 was a strong predictor of adverse events in post-Whipple patients. Also, we assessed the ability of MEWS to predict postoperative complications with an accuracy rate of 90.86–91.23%, a sensitivity of 83.04–90.88%, and a specificity of 90.85–95.73%. The results attest to the reliability of our MEWS as a screening tool. In comparison to similar studies around the world, our study used both retrospective observational studies and
prospective confirmatory studies.
Additionally, most studies have previously focused on
the use of MEWS to assess criteria for patient access to the
ICU, and we are the first international study to predict and
check postoperative complications. Moreover, we used a
tremendous amount of data, and the data we included came
from different time points during the hospitalization of
patients. This is also the first international study of MEWS
using the data of vital signs measured at random times,
which makes the clinical application more accessible and
more efficient. Finally, our project is the first attempt to use
MEWS as a prognostic indicator in postoperative patients.

It is inexpensive, convenient, and less invasive than any
scoring system used in other papers. The predictive values
of MEWS in this study are comparable to the advanced
mathematical models, but MEWS is more convenient,
accessible, and more applicable.
