Many women with early-stage breast cancers experience bone loss, and some are at increased risk of osteoporosis. The mechanisms are age-related bone loss and estrogen deprivation either through the development of chemotherapy-induced ovarian failure (CIOF) (1), or receiving aromatase inhibitors (2). The third generation amino-bisphosphonate zoledronic acid (ZA), and the receptor activator of nuclear factor-κB ligand (RANKL) inhibitor, denosumab, effectively prevent or treat osteoporosis in these settings (3). What is less clear is whether bone-modifying agents (BMAs) have clinically significant anti-cancer effects despite data that provides the underlying rationale for testing it in the clinic.

ZA and denosumab are used to treat skeletal metastases based on a reduction in skeletal-related events such as spinal cord compression, pathological fracture, and the necessity for radiation or surgery to bone (3). Figure 1 explains how these drugs work. The regulation of bone mass involves two levels: at the “macro” level, the control is through systemic hormones (e.g., androgens, estrogens, calcitonin, and parathyroid hormone), and the mechanical forces imposed by gravity. The “micro” level occurs in the bone-remodeling unit, comprised of two primary cell types. Osteoblasts, derived from mesenchymal precursor cells, are responsible for new bone formation, whereas osteoclasts derived from hematopoietic precursor cells are responsible for bone resorption.

The dynamic balance between osteoblast and osteoclast function regulates new bone formation and resorption (4). The osteoblast is the master regulator of bone-remodeling unit secreting both osteoprotegerin (OPG, also called osteoclastogenesis inhibitory factor, a member of the tumor necrosis factor receptor superfamily), and RANKL. When RANKL binds to RANKL receptor located on osteoclast precursor cells, it causes differentiation into mature osteoclasts and stimulates the multiple mechanisms by which bone resorption occurs. The osteoblast also secretes OPG that acts as a decoy receptor for RANKL, thus putting the brakes on osteoclasts. Also, T-cells play critical roles in maintaining bone mass. Estrogen deficiency of normal menopause causes T cells to secrete tumor necrosis factor-alpha and RANKL that activate osteoclasts, causing bone resorption (5,6).

In bone loss and osteoporosis, as well as tumors metastasizing to the bone, osteoclasts are activated, and bone resorption occurs (Figure 1). ZA inhibits osteoclast differentiation, inhibits the binding of the activated osteoclast to the bone surface, and inhibits the lysosomal secretion of hydrochloric acid, one of the major mechanisms of bone resorption. Denosumab is a humanized monoclonal antibody to RANKL. By binding to RANKL, it inhibits osteoclasts.

Experimentally ZA and RANKL inhibition reduce the induce of skeletal metastases in animal models (7,8). Disseminated tumor cells (DTCs) reside in the bone marrow and contribute to other sites of metastases (9). DTCs serve as a prognostic factor in early breast cancer (10), and ZA can reduce DTCs in the human bone marrow (11,12). The preclinical and clinical data support the hypothesis that BMAs have anti-cancer effects, and a series
of clinical trials tested this hypothesis.

It is instructive to review trials that examined ZA, the Austrian Breast Cancer Study Group (ABCeSG) trial 12 (13), AZURE (14), and National Surgical Adjuvant Breast and Bowel (NSAPB) B-34 trials that examined oral clodronate (15). ABCSG trial 12 was the first clinical trial to describe the anti-cancer effects of ZA. Eighteen-hundred and three premenopausal women with stages I and II breast cancers received goserelin, a gonadotrophin-releasing hormone (GnRH) antagonist, that rendered them “chemically” postmenopausal. The women were randomized in a 2×2 factorial design to receive tamoxifen or anastrozole, with or without ZA. The primary endpoint was disease-free survival (DFS). The dose and schedule of ZA was 4 mg IV every six months for three years, or a total of 6 doses. At a median follow-up of nearly eight years, the DFS was 88.4% and 85.0%, in ZA and control arms, respectively [hazard ratio (HR) =0.77; 95% CI: 0.60 to 0.99, P=0.042]. There were fewer locoregional (2.7% vs. 4.4%), distant (6.0% vs. 7.1%), and bone (2.7% vs. 3.5%) recurrences in the ZA-treated women. The overall survival (OS) was numerically better in ZA treatment (96.7% vs. 94.5) but not statistically significant with the HR of 0.66 (95% CI: 0.43 to 1.12, P=0.06).

The AZURE trial was a phase III open-label of ZA added to standard adjuvant therapy in 3,360 women with stage II and III breast cancer patients. The schedule of ZA was intensive, with 19 doses over five years. Unlike ABCSG trial 12, there were no differences in DFS and invasive DFS with a median of 63 months follow-up. However, in a pre-planned subset analysis, there was a statistically significant interaction with menopausal status. The invasive DFS was 78.2% vs. 71% (adjusted HR =0.75, 95% CI: 0.59 to 0.96, P=0.02), and overall survival was 84.6% vs. 78.7% (adjusted HR =0.74, 95% CI: 0.55 to 0.98, P=0.04) in women more than five years postmenopausal. The specific events were less locoregional, second invasive primary breast cancers, and distant recurrences for ZA-treated women. Curiously, distant recurrences in bone did not differ between the postmenopausal treated with ZA and controls.

NSABP B-34 was a phase III randomized, double-blind, placebo-controlled trial using oral clodronate, a less potent first-generation bisphosphonate not available in the US, in 3,324 women (65% over the age of 50 years) receiving adjuvant therapy. The oral clodronate/placebo was 1,600 mg per day for three years. With a median follow-up of eight
years, like the AZURE trial, there were no differences in DFS or OS in the entire trial population. However, in women over 50 years old who received clodronate the bone-metastasis free-interval (HR =0.62 95% CI: 0.40 to 0.95), non-bone metastasis-free interval (HR =0.63 95% CI: 0.43 to 0.91), and the recurrence-free interval (HR =0.75 95% CI: 0.57 to 0.99) were all statistically significant.

AZURE and NSABP B34 are the largest of the trials of bisphosphonates in the adjuvant setting. Several aspects of these trials raised questions. What about the many premenopausal who went into CIOF? CIOF frequently occurs (40–60% of women depending on their age when starting chemotherapy) and rapidly (within 6-12 months) in premenopausal women (1). These women would be rendered postmenopausal, yet the anti-cancer effect was not observed in premenopausal women. Considering the underlying mechanism and preclinical data, one would predict that ZA would reduce bone metastases. However, in the AZURE trial using ZA on an intensive schedule akin to the treatment of bone metastases (19 vs. 24 treatments), showed no reduction in bone metastases. Whereas, using less potent oral clodronate in the NASBP B-34 trial, or using ZA on a much less intensive schedule as in the ABCSG trial 12, did show a reduction in bone metastases.

Conflicting results in other trials led the Early Breast Cancer Trialist Collaborative Group (EBCCG) to perform a meta-analysis of seventeen randomized trials of ZA vs. control/placebo in over 17,000 women (16). Among the over 6,000 premenopausal women, the effect on disease outcomes was nil. However, among the more 11,000 postmenopausal women, treatment with ZA led to fewer bone recurrences (HR =0.72 95% CI: 0.60 to 0.86, P=0.0002), and breast cancer mortality (HR =0.82 95% CI: 0.73 to 0.93, P=0.002). At ten-years, the absolute reductions in bone recurrences were 2.2%, and in breast cancer mortality were 3.3%.

The National Comprehensive Cancer Center Network (17), American Society of Clinical Oncology (18), European Society of Medical Oncology (19) and St. Gallen’s Conference (20) guidelines say “consider” ZA use postmenopausal women, especially in women with a high risk of metastatic disease. Despite these recommendations, only about forty percent of oncologists say they routinely add bisphosphonates to adjuvant therapy solely for the anti-cancer effect, independent of prevention or treatment of osteoporosis (20). Why is this so? The possibilities include it is unclear what is a sufficiently high risk of distant recurrences to justify adding ZA as part of adjuvant therapy. One node-positive, three-nodes positive, or ten-nodes positive? Also, to observe the anti-cancer effects, the number of doses of ZA is unclear. Six-doses of ZA over three years as in ABCSG trial 12 (13) or nineteen-doses over a five period as in the AZURE trial (14)? Finally, why should the effect only work in a low estrogen environment?

BMA agents have side-effects too, the most serious of which is the dose and duration-dependent osteonecrosis (21). Osteonecrosis is most often observed in the treatment of metastatic bone disease, where the rates for both ZA and denosumab are in the 1–2% range. In the AZURE trial using an intensive schedule of ZA, the cumulative percentage of osteonecrosis was 1.1% (14). Whereas in the ABCSG trial 12, osteonecrosis was not observed.

Now let’s turn to the data supporting denosumab as an anti-cancer drug. First, in the treatment of bone metastases, denosumab was superior to ZA in time to first and subsequent skeletal-event analysis (22,23). Although, some have questioned the superiority denosumab over ZA as there was no difference in survival nor some of the individual skeletal-related events (24). Also, denosumab was much less cost-effective than ZA (25). The ease of administration via the subcutaneous route and "superiority" in the treatment of bone metastases may be responsible for denosumab’s broad acceptance by the oncologic community.

The Austrian Breast Cancer Study Group (ABCSG) trial 18 is instructive to review (26). ABCSG trial 18 was a double-blind, placebo-controlled trial of denosumab/placebo in 3,425 postmenopausal women receiving an aromatase inhibitor. The primary endpoint was a reduction in fractures. Exploratory analyses were disease-free and bone metastasis-free survival. Notably, the schedule of denosumab was every six months for five years or a total of 10 treatments. The primary endpoint was met, with a median of 73 months, the secondary endpoint of DFS was better on denosumab arm with HR of 0.82 (95% CI: 0.69 to 0.98). To make the hazard rate more clinically relevant, at eight years, the improvement in DFS was an absolute 3% difference (80.6% versus 77.5%).

Looking at the specific events in trial ABCSG trial 18, there were no differences in histologically-verified invasive local-regional recurrences, distant recurrences, contralateral new primary cancers, or ductal carcinoma in situ. The superior DFS in the denosumab-treated women was the non-histologically verified distant metastases or new primary breast cancers. One could argue that the double-blind, placebo-controlled design, and the intention-to-treat analysis, would minimize bias. Still, possibly chance
or unknown imbalances existed to make the numbers of histologically unverified new primary breast cancers (100 vs. 80) and distant recurrences (68 vs. 56) higher in placebo-treated patients.

With the above as background, the recently published Amgen-sponsored, double-blind, placebo-controlled adjuvant denosumab in early breast cancer or D-CARE trial comes into view (27). The primary hypothesis was denosumab added to standard of care adjuvant, or neoadjuvant therapy would improve bone metastasis-free survival over that of standard care therapy plus placebo. The event-rate, as in all phase III clinical breast cancer trials, was lower than predicted. Rather than increase the sample size, the sponsors decided to change the trial analysis from an event-driven analysis (where the events were bone metastasis) to a time-driven analysis when all the trial participants completed a minimum of 5 years of follow-up.

From 2010 to 2012, 4,509 women were randomized. The median age was 50 (range, 44–59), 54% were postmenopausal, 93% were N1-N3, and the trial included all breast cancer subtypes in the expected frequencies. The schedule of denosumab was intensive, initially monthly for six months, then every three months for 4.5 years, and the median number of doses received was 25 (range, 1–26) out of a planned 26 treatments. The primary endpoint, bone recurrences was not different for denosumab and placebo groups with the hazard ratio (HR) 0.97 (95% CI: 0.82 to 1.14), P=0.70, and the secondary endpoint, disease-free survival was not different (HR 1.04; 95% CI: 0.91 to 1.19, P=0.57). They presented the results of a pre-planned subset analysis, and there were no differences by menopausal status.

With the uncertainties of ABCSG trial and wholly negative D-CARE trial, denosumab should not be used as an anti-cancer drug. There are several ongoing trials of denosumab as an anti-cancer drug in the neoadjuvant setting, in aromatase inhibitor-induced bone loss, or the schedule of administration that are either fully enrolled but not reported as yet or actively recruiting (http://ClinicalTrials.gov). Hopefully, more information may be forthcoming. In terms of ZA, data are supporting its’ use as an anti-cancer drug. However, several outstanding questions remain, including which specific population of high-risk postmenopausal women and the schedule of administration. However, it is unlikely that future trials will be dedicated to answering these questions.

Different oncologists will interpret the data described above in different ways. In the low risk, estrogen receptor-positive, node-negative postmenopausal women, or women rendered postmenopausal by treatment with a GnRH agonist, the benefits of ZA maybe not justified because of a favorable prognosis. In contrast, in high-risk, multiply node-positive, higher-stage women, the data on ZA may be compelling. For women with breast cancer who at risk of developing osteoporosis or have established osteoporosis, using ZA every six months will build bone and improve the T-scores and may help reduce recurrences in bone and improve mortality.
