Abstract: Metal-on-metal (MoM) bearing surfaces were historically used for young patients undergoing total hip arthroplasty, and remain commonplace in modern hip resurfacing. A substantial number of female patients with MoM bearings subsequently gave birth following implantation of the bearings before a full understanding of metal ions exposure in these patients was established. In theory, it has been postulated that metal ions released from such implants may cross the placental barrier and cause harm to the fetus. In light of this potential risk, recommendations against the use of MoM components in women of child-bearing age have been advocated. The purpose of this systematic review was to evaluate: (I) the MoM bearing types and ion levels found; (II) the concentrations of metals in maternal circulation and the umbilical cord; and (III) the presence of abnormalities in the fetus or delivered child. A comprehensive literature review was conducted of studies published between January 1st, 1975 and April 1st, 2019 using specific keywords. We defined the inclusion criteria for qualifying studies for this review as follows: (I) studies that reported on the women who experienced pregnancy and who had a MoM hip implant; (II) studies that reported on maternal metal ions blood and umbilical cord levels; and (III) studies that reported on the occurrence of fetal complications. Data on cobalt and chromium ion levels in the maternal blood and umbilical cord blood, as well as the presence of adverse effects in the infant were collected. Age at parturition and time from MoM implant to parturition were also collected. A total of six studies were included in the final analysis that reported on a total of 21 females and 21 infants born. The mean age at parturition was 31 years (range, 24 to 41 years), and the mean time from MoM implantation to parturition was 47 months (range, 11 to 119 months). Maternal blood cobalt levels were found as a weighted average of 34.09 ug/L (0.425 to 138 ug/L), while umbilical cord blood cobalt levels were found to be 22.61 ug/L (0.52 to 51.11 ug/L). Cobalt levels were reduced by an average of 34% between maternal and umbilical cord blood. Maternal cord blood chromium levels were found as a weighted average of 18.18 ug/L (0.225 to 75 ug/L), while umbilical cord chromium levels were found to be 3.96 ug/L (0.14 to 11.96 ug/L). Chromium levels were reduced by an average of 78% between maternal and umbilical cord blood. No cobalt or chromium was detected in the umbilical cord blood of three patients. Out of the 21 infants born to women with MoM implants, 20 were born healthy with no adverse effects or complications. Only one complication was recorded in single infant that did not appear to be related to the maternal MoM implant. To date, there is a lack of consensus as to whether MoM hip arthroplasty implants are to be avoided in the child-bearing female population and whether they constitute a hazard to the fetus *in utero*. Both chromium and cobalt ions were markedly reduced in levels when transitioning from maternal to cord blood. In particular, chromium showed a greater reduction on average than cobalt (78% vs. 34%). Based on the current evidence, there appears to be no correlation between the presence of metal ions in umbilical cord blood and complications, as none of the infants experienced abnormalities uniquely attributable to the presence of metal ions.

Keywords: Cobalt; chromium; hip arthroplasty; implants; pregnancy; metal-on-metal (MoM)

Introduction

Metal-on-metal (MoM) hip prostheses were used historically in total hip arthroplasty and are still used in hip resurfacing. Despite initial wide spread utilization (1,2), multiple studies have raised concerns about excessive release of metal ions from these prostheses into the systemic circulation along with increased risk of fretting, corrosion, and adverse local soft tissue reactions (3,4). In some reports, it was postulated that pregnant women who have elevated metal ion levels may be at increased risk of mutagenic, teratogenic, or acute fetotoxic effects in their offspring if metal ions crossed the placental barrier (5). In light of this potential risk, recommendations against the use of MoM components in women of child-bearing age have been advocated (6-9).

Despite the historical practice of using MoM hip implants in women of child-bearing age, there remains a contemporary theoretical dilemma concerning their effect on fetuses of pregnant women who may have undergone MoM-THA or hip resurfacing (6). However, the true clinical importance of elevated metal ion levels in these women remains uncertain. Therefore, the purpose of this systematic review was to elucidate the survivorship associated with MoM implants in gravida women. Specifically, we evaluated: (I) the MoM types and ion levels observed; (II) the presence of maternal and umbilical cord levels of the metals; and (III) the presence of abnormalities in the fetus or delivered child.

Methods

A comprehensive literature search was conducted of studies published between January 1st, 1975 and April 1st, 2019 concerning MoM hip resurfacing and THA and pregnancy. The following databases were queried: PubMed, EBSCOhost, and EMBASE. The following keywords were used in combination with Boolean operators AND or OR for the literature search; “metal-on-metal,” “pregnancy,” “hip,” “metal ions,” “cobalt,” “chromium,” “arthroplasty,” “resurfacing,” “arthroplasty,” “malformations,” and “complications.” Inclusion criteria for qualifying studies

were defined as follows: (I) studies that reported on the women who experienced pregnancy and who had a MoM hip implant; (II) studies that reported on maternal metal blood levels and umbilical cord metal levels; and (III) studies that reported on the congenital malformation status of the infant. Umbilical cord metal ion levels were determined at delivery. Additionally, we excluded: (I) duplicate studies among searched databases and (II) previous reviews. Data on cobalt and chromium ion levels in the maternal blood and umbilical cord blood, as well as the presence of congenital malformations or other abnormalities in the infant, were collected. Age at parturition and time from MoM implantation to parturition were also collected. The selection process is summarized in *Figure 1*.

A total of six studies met our criteria (6-11). They reported on twenty-one females with MoM prostheses, who gave birth to twenty-one infants. The mean age at parturition was 31 years (range, 24 to 41 years), and the mean time from MoM implant to parturition was 47 months (range, 11 to 119 months). All studies prospectively enrolled pregnant patients with MoM implants. Three studies included a control group comprised of perinatal women with no metal implants (9-11). Concentrations of cobalt and chromium in both maternal and umbilical cord blood at parturition were determined in all twenty-one patients utilizing routine methodology previously published on (12,13). All studies evaluated infants for effects of teratogens and general health shortly after birth. Findings from the individual studies are summarized in *Table 1*.

Results

Metal ion levels in mothers and infants

Maternal blood cobalt levels were found as a weighted average of 34.09 ug/L (range, 0.425 to 138 ug/L), while umbilical cord blood cobalt levels were found to be 22.61 ug/L (range, 0.52 to 51.11 ug/L). Cobalt levels were reduced by an average of 34% between maternal and umbilical cord blood. Maternal cord blood chromium levels were found as a weighted average of 18.18 ug/L (range, 0.225 to 75 ug/L), while umbilical cord chromium

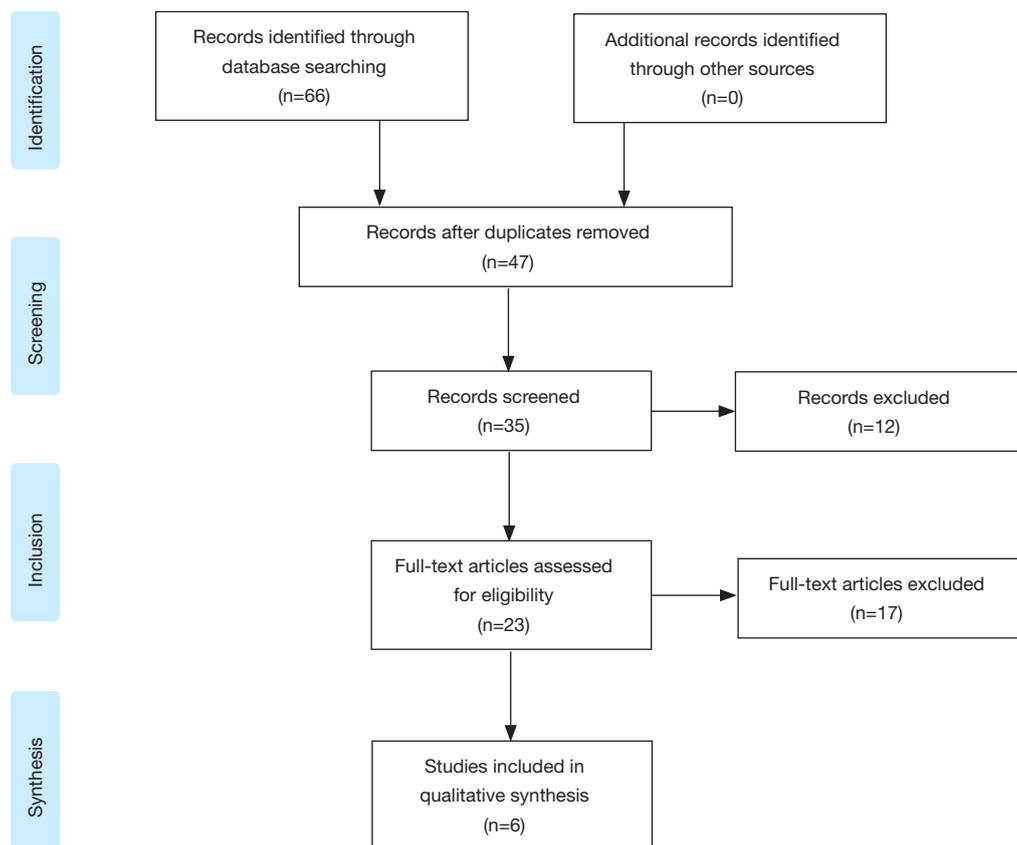

Figure 1 Flow diagram of selection process for articles in this review.

levels were found to be 3.96 ug/L (range, 0.14 to 11.96 ug/L). Chromium levels were reduced by an average of 78% between maternal and umbilical cord blood. No cobalt or chromium was detected in the umbilical cord blood of three patients.

Comparison to controls

Two studies compared maternal and fetal blood measurements to control cohorts. In the study by Ziaee *et al.* (11), maternal blood cobalt and chromium measured 1.39 and 1.28 $\mu\text{g/L}$ in MoM patients *vs.* 0.34 and 0.199 $\mu\text{g/L}$ in the control cohort. Umbilical cord blood concentrations of cobalt and chromium measured 0.839 and 0.378 $\mu\text{g/L}$ in MoM patients *vs.* 0.336 and 0.194 $\mu\text{g/L}$ in the control cohort. Novak *et al.* (9) recorded similarly high measurements in the maternal and fetal blood samples of MoM patients. Maternal cobalt and chromium averaged as low as 0.2 and 0.1 ng/mL while in the fetal cord blood they

averaged 0.15 and 0.09 ng/mL.

Infant outcome

Out of the 21 infants born to women with MoM implants, 20 were born healthy with no complications. One infant was malformed at birth with craniofacial dysplasia (microphthalmia, microtia), cerebral anomalies, and isthmic aortic stenosis with an open aortic duct, bowel malrotation, a hyperplastic thymus, and flexion contractures of both hands (7). This infant suffered mortality one week post-partum.

Discussion

Historically, women of childbearing age constituted a considerable portion of younger patients undergoing MoM hip arthroplasty (6). Currently, MoM implant use

Table 1 Metal-on-metal hip implants studies and findings

Authors (year)	# of patients	Metals	Birth abnormalities	Cord blood levels detected	Average chromium detected in mother (ug/L)	Average cobalt detected in mother (ug/L)	Average chromium detected in umbilical cord (ug/L)	Chromium reduction from maternal blood to cord blood (%)	Average cobalt detected in umbilical cord (ug/L)	Cobalt reduction from maternal blood to cord blood (%)
deSouza et al. [2012] (8)	3	Cobalt, chromium	0/3	3/3	44.22	38.82	10.03	77.3	18.61	52.1

is now obsolete in this patient population due to concerns over the potential effects of elevated metal ion levels on fetal development, as well as the contraindication of some devices in females. At the present time, no evidence exists to definitively recommend for or against the use of MoM hip bearing surfaces in female patients of childbearing age. Our analysis aimed to address this void, through the first and only systematic review focused on the effects of MoM implants in women of childbearing age. Specifically, our review evaluated: (I) the MoM bearing types and ion levels observed; (II); the concentrations of metals in maternal circulation and the umbilical cord; and (III) the presence of abnormalities in the fetus.

The present analysis suggests that elevated levels of circulating cobalt and chromium in pregnant women with MoM implants may cross the placental barrier and lead to elevated levels of these metals in fetal circulation. Detectable levels of cobalt and chromium were found in umbilical cord blood in all cases except 3 (of 3) patients analyzed by Brodner *et al.* (7). This study used graphite furnace atomic absorption spectrometry, however, which is not as sensitive for metal ion detection compared to other standard analytical techniques (i.e., high-resolution inductively-coupled plasma mass spectrometry). In all of the included studies, authors rose concerns about the higher than normal concentrations of metal ions in the maternal cord blood. However, they failed to demonstrate a clinically relevant complication or abnormality in the fetus.

Despite trans-placental passage of chromium and cobalt, the placenta appears to exert a modulatory effect which reduces their concentration in fetal blood relative to maternal blood. This effect was demonstrated to be greater for chromium than cobalt, although levels of both metals were markedly reduced after placental transfer. It is known that control of substance transfer is a primary function of the placenta (7). Inherently, the modulation of heavy metal ions passing across the placenta likely represents normal physiology, as trace amounts of these ions are necessary for fetal development (11). Several studies have demonstrated the modulatory function of the placenta in transferring metal ions between mother and fetus (13-15). This modulation differs depending on the specific metal traversing the placenta, as the placenta demonstrates an ability to facilitate passage, limit passage, or establish a concentration gradient of specific ions (15). Our analysis supports these known functions of the placenta by demonstrating its ability to limit the transfer of both cobalt and chromium to the fetus.

Although MoM hip prostheses in pregnant women may lead to elevated chromium and cobalt levels in their offspring, the clinical relevance of these elevations is uncertain. Industrial exposure to cobalt and chromium has been shown to have cardiac, renal, ophthalmic, immunologic, reproductive, and carcinogenic effects (16). However, limited evidence exists to suggest that similar effects are found in hip arthroplasty procedures, where the degree of exposure is lower and the mechanism of exposure is distinctly different (16-19). Reports of adverse local tissue reactions and acute systemic effects associated with ion release from MoM implants exist (20-27), however, the incidence and specific etiology of these reactions or effects remain elusive. Moreover, the long-term effects of chromium and cobalt release from metal prostheses are undetermined.

Our analysis suggests elevated levels of circulating chromium and cobalt in pregnant women with MoM prostheses present no identifiable threat to fetal health. Twenty out of twenty-one infants in the included studies were born healthy, without any noted malformations. As reported by Brodner *et al.*, one infant was born substantially malformed and non-viable. The relationship between this infant's malformities and the mother's MoM implants may represent simple correlation versus identifiable causation. This specific mother gave birth to three children prior to receiving her MoM implant, two of which were malformed in a similar manner to the infant in the study. These two children were also from the same partner as her final malformed child born during the study, while her healthy child was from a different father (7). Another infant reported by Oppermann *et al.* was born with mild hypospadias (10), a common birth defect of multifactorial etiology (10,28). Although other studies have found a link between hypospadias and high blood levels of cadmium and lead (29), a similar association has not been demonstrated for chromium or cobalt. Aside from the hypospadias, this infant was otherwise healthy and developed normally.

Our analysis aimed to characterize the effects of MoM hip bearing surfaces and circulating metal ion levels in women of childbearing age, specifically regarding these effects on fetal health. The results of this analysis suggest MoM hip prostheses are likely well-tolerated in women of childbearing age and do not present an identifiable threat to fetal health. Although chromium and cobalt released from MoM implants cross the placental barrier, this process is modulated by specific mechanisms which decrease the

amount of ions entering fetal circulation.

Moreover, the presence of metal in umbilical cord blood was not correlated with congenital malformations in the fetus, as none of the infants experienced congenital abnormalities uniquely attributable to the presence of metal. This review was limited by the methodological quality of its inclusion studies, all of which had relatively small sample sizes and did not track mother or infant health over the long term. To our knowledge, however, this analysis represents the most comprehensive investigation to date regarding the safety of MoM implants in women of childbearing age. Future studies should focus on analyzing larger sample populations, and tracking patients over longer periods of time.
